ABSTRACT

Unlike applets, traditional systems programs written in Java place significant demands on the Java runtime and core libraries, and their performance is often critically important. This paper describes our experiences using Java to build such a systems program, namely, a scalable web crawler. We found that our runtime, which includes a just-in-time compiler that compiles Java bytecodes to native machine code, performed well. However, we encountered several performance problems with the Java 1.1 core libraries, including excessive synchronization, excessive allocation, and other programming inefficiencies. The paper describes the most serious pitfalls and how we programmed around them. In total, these workarounds more than doubled the speed of our crawler.

Keywords

Java performance, Java class libraries, web crawling

1. INTRODUCTION

This paper describes our experiences using Java to build Mercator, a scalable web crawler. Web crawlers have many of the characteristics of classical systems programs: they run for days or weeks at a time, use large amounts of memory, have significant I/O requirements, must perform well, and need to be fault-tolerant. These requirements place very different burdens on the programming libraries and runtime environment than Java applets do.

When we started this project, we were not sure if our Java runtime environment or the Java core libraries were indeed suitable for such a systems program. In the process of implementing and optimizing Mercator, we were pleased to find that the "just-in-time" (JIT) compiler we used was quite efficient. In the latest version of the crawler, only about one third of the CPU cycles are spent executing compiled bytecode; the remaining cycles are spent in the Java runtime or executing native methods. As a matter of fact, half of all Mercator's cycles are spent in the Unix kernel.

However, we also discovered that in many places, the Java core libraries traded off performance for ease of use. While this tradeoff is quite sensible for interactive applications such as applets, it is problematic for classical systems programs. The focus of this paper is on the performance problems we discovered in the Java core libraries, and the methods we used to overcome them.

The remainder of the paper is structured as follows. Section 2 describes the tools we used to develop Mercator. Section 3 describes its main characteristics, focusing on its system requirements. The bulk of the paper, Sections 4–6, enumerates the performance problems we discovered in the Java core libraries, describes how we programmed around them where possible, and quantifies the performance improvements that resulted. Finally, Section 7 offers our conclusions.

2. OUR DEVELOPMENT TOOLS

The performance of any Java program depends on the compiler that produced its bytecodes, and on the Java runtime under which it is run. A variety of tools are available for debugging the performance of Java programs, such as Intel's *VTune* [11], Intuitive Systems' *OptimizeIt* [10], KL Group's *JProbe* [8], and IBM's *Jinsight* [7]. In this section, we describe the development tools we use and their features for measuring various performance properties of Java programs.

We use a standard Java compiler, namely, the Symantec Visual Cafe compiler. All of our coding, compiling, and small-scale testing is done on Wintel PCs.

Our production runs and large-scale tests are done on multiprocessor Alpha machines running Compaq's Tru64 Unix operating system. For all our runs on this platform, we use a prototype in-house Java runtime called *srcjava*. The srcjava runtime uses an unmodified copy of Sun's JDK 1.1.4 class libraries. It includes a JIT compiler that generates straightforward Alpha machine code from Java bytecode with little optimization. One of srcjava's strengths is that its implementation of Java's synchronization primitives (i.e., locks and condition variables) are both time- and space-efficient, especially in the absence of lock contention.

2.1 srcjava performance debugging support

srcjava can also be used as a performance debugging tool. It has command-line switches for measuring and reporting several aspects of a program's run-time performance. This section illustrates these features on a simple multi-threaded program that allocates a central hash table and then forks several worker threads. Each thread repeatedly picks a ran-

dom number, converts the number to a string using Java's *Integer.toString* method, and then inserts the string into the global hash table.

Synchronization. srcjava can print information about a program's lock acquisitions. It uses stack traces to identify acquisition sites. As a result, the same *synchronized* statement may produce multiple entries. For each acquisition site, srcjava prints the number of lock acquisitions performed at that site. The synchronization data is printed at the end of the run. Here is the first entry for the test program:

```
8483  7: java.lang.StringBuffer.append(C)
     64: java.lang.Integer.toString(II)
      3: java.lang.Integer.toString(I)
     19: test.TestAllocSync$Worker.run()
```

This entry shows that 8,483 lock acquisitions were performed at the site identified by the stack trace. The second column is the bytecode offset within each of the listed methods. srcjava can also collect and report information about lock contention, but we do not describe that feature here.

Allocation and garbage collection. srcjava can print the number and total size of all allocations made over the life of a program. For each allocation site (again identified by its stack trace), the output lists the type of the allocated object, the number and total size of allocations at that site, and the site's stack trace. The allocation profile is printed at the end of the run. Here is the first entry for our test program:

```
1000  40000  20.4%  [C
    java.lang.StringBuffer.<init>(I)
    java.lang.Integer.toString(II)
    java.lang.Integer.toString(I)
    test.TestAllocSync$Worker.run()
```

This entry indicates that 1,000 character arrays were allocated at the allocation site reached through the listed stack trace, for a total of 40,000 bytes, or 20.4% of the program's total allocation.

One cost of excessive allocation is increased garbage collection (GC). srcjava can print the elapsed time spent on each collection, as well as the total GC time.

Heap Profile. srcjava provides two mechanisms for reporting on the contents of the heap. First, it can print a type-based profile of the heap before and after each GC. This profile is rather flat, but it can still be quite useful. The post-GC profile gives a profile of the live heap. For example, here is the post-GC profile for our test program (only the top five entries are shown):

```
  Bytes Objects   Sizeof Space% Type
3458656   86512     8-64 43.72% [C
2076096   86504       24 26.25% java.lang.String
1889448   78727       24 23.89% java.util.HashtableEntry
 417800       1 256K-2M  5.28% [Ljava.util.HashtableEntry
  32800       2   4K-32K  0.41% [C
```

Note that array types are divided into different groups, based on their sizes (in bytes). In this example, there are two entries for character arrays. srcjava can also produce a more structured breakdown of the live heap based on reachability paths.

2.2 DCPI

The other tool we frequently use for performance debugging is DCPI, the Digital Continuous Profiling Infrastructure [1, 6]. DCPI is a freely-available profiling tool that runs on Alpha systems. It uses counters built into the Alpha processor, and it can profile code running in both user space and the kernel. Moreover, DCPI's profiling overhead is quite low, typically 2%–6%.

We use DCPI to get CPU cycle breakdowns of Mercator. By virtue of DCPI's universal sampling, we can simultaneously profile the srcjava runtime, compiled bytecode, and native methods, including kernel routines. In addition to its profiling core, DCPI also includes tools for printing CPU cycle breakdowns at various granularities, including whole images, functions, and individual instructions. Here is the image-level breakdown for one run of our test program:

```
cycles      %  image
 37171  41.67%  /vmunix
 32509  36.45%  TestAllocSync.exe
 19512  21.88%  srcjava
```

Here are the top 10 functions in the function-level breakdown for the same run. The first 4 functions are all related to synchronization.

```
cycles      %  procedure              image
  5063  5.68%  comp_sync_exit         TestAllocSync.exe
  4725  5.30%  comp_sync_enter        TestAllocSync.exe
  3466  3.89%  comp_sync_exit_endopt  TestAllocSync.exe
  3321  3.72%  comp_sync_enter_endopt TestAllocSync.exe
  2415  2.71%  nofault_bcopy          /vmunix
  2254  2.53%  checksig               /vmunix
  1841  2.06%  comp__OtsDivide32      TestAllocSync.exe
  1640  1.84%  thread_block           /vmunix
  1635  1.83%  java.util.Hashtable.put TestAllocSync.exe
  1535  1.72%  move                   srcjava
```

3. THE MERCATOR WEB CRAWLER

Mercator is designed to be extensible and scalable. By extensible, we mean that Mercator is designed in a modular way, with the expectation that new functionality will be added by third parties. We use Java's dynamic class loading facilities to load user-supplied modules at run-time. By scalable, we mean that it should be able to crawl a web of indefinite size while using a bounded amount of memory. In practice, we recently used Mercator to download 30 million web documents over the course of 12 days; during this crawl, the live Java heap size was limited to 150-200 MB. The bulk of Mercator's data structures are stored on disk; in production crawls, they often amount to tens of gigabytes.

Mercator is highly multi-threaded, typically using 100 threads to fetch and process web pages in parallel. Java's support for multi-threading allows us to use synchronous socket operations, which significantly simplifies the code, and allows our crawling process to utilize all the processors of a multi-processor machine. By comparison, other crawlers documented in the literature [3,5] are single-threaded and achieve concurrent downloads via asynchronous I/O, which is somewhat awkward to program.

Mercator's I/O requirements are also indicative of a classical systems program. It uses TCP sockets to download documents (with peak download rates of hundreds per second),

UDP sockets to perform domain name service (DNS) resolutions, and both sequential and random-access files to access its large disk-based data structures.

For portability, Mercator is written in 100% pure Java. We run it on both Wintel PCs and Alpha Unix workstations. It is a medium-sized Java program; its Java source files (including test classes and comments) total 20,000 lines.

When crawling the world wide web, we found that the responsiveness of web servers fluctuates greatly over time, making it hard for us to measure Mercator's end-to-end performance in a repeatable fashion. We therefore wrote a program that, from Mercator's point of view, acts like an HTTP proxy, but synthesizes web pages instead of actually fetching them. We used this "web synthesizer" to measure the end-to-end performance of the initial and optimized versions of Mercator. Overall, the optimizations described in the following three sections more than doubled Mercator's download rate.

4. EXCESSIVE SYNCHRONIZATION

Writing correct multi-threaded programs is far from trivial; it requires training and discipline [2]. Most programmers have not been exposed to programming with threads, and therefore lack the needed experience. Presumably for this reason, the designers of the Java core libraries decided to minimize the likelihood of race conditions by making many of the core classes thread-safe. This was done by declaring the classes' public methods to be *synchronized*. By doing so, they sacrificed performance for ease of use, since many of the lock acquisitions that result from this approach are unnecessary.

In practice, this tradeoff can lead to large performance penalties. Using DCPI, we determined that Mercator initially spent about 20% of its cycles on synchronization-related operations. After we applied the optimizations described below, the fraction of cycles spent on synchronization fell to 1.5%.

4.1 StringBuffers

The over-synchronization problem is exacerbated if the class in question is a low-level class with many clients. The best example is the class *java.lang.StringBuffer*, all of whose public methods are synchronized. The Java 1.1 compiler uses *StringBuffers* to implement the string concatenation operator +. For example, the expression *"foo"+"bar"* is translated to:

new StringBuffer().append("foo").append("bar").toString()

Evaluating this expression results in 3 lock acquisitions (one for each of the method calls), even though there is no potential for race conditions, since the *StringBuffer* is accessible from only one thread.

To make matters worse, *StringBuffers* are used by many other low-level Java classes. For example, the methods *Integer.toString* and *Long.toString* use *StringBuffers* to convert numbers into strings. In so doing, they perform $n+2$ lock acquisitions, where n is the length of the resulting string.

These methods in turn are called by overloaded versions of the *StringBuffer.append* method. For example, the expression *"THX"+1138* uses *Integer.toString* to convert 1138 into a string, resulting in 6 lock acquisitions, and then performs 3 more acquisitions to compute the final result.

The previous example is by no means artificial. For example, *InetAddress.getHostAddress*, which converts an IP address to a string, is implemented in exactly this way. As a result, converting the address 172.18.229.100 into a string requires 27 lock acquisitions, all of which are unnecessary!

Concatenating strings and converting numbers and IP addresses to strings are common operations in Mercator, so *StringBuffers* showed up prominently in srcjava's synchronization profile. To avoid the unnecessary lock acquisitions introduced by *StringBuffer*, we implemented a *Formatter* class that combines *StringBuffer* functionality with facilities for formatting various types (subsuming for instance *Integer.toString*). The use of *Formatters* significantly reduces Mercator's lock acquisition rate; it also avoids unnecessary heap allocations, as described below in Section 5.

Sun could easily address these issues by providing an unsynchronized variant of *StringBuffer*, and by changing the implementations of the string concatenation operator + (in the *javac* compiler) and the methods *Integer.toString*, *Long.toString*, etc. to use this unsynchronized variant.

4.2 I/O Streams

The *java.io* package provides a stream abstraction for performing byte I/O, and a reader/writer abstraction for performing Unicode character I/O. Both abstractions are designed to be composable; for example, the standard way to read a sequence of integers from a file is to compose a *FileInputStream* (to access the file) with a *BufferedInputStream* (to avoid excessive kernel calls), which in turn is composed with a *DataInputStream* (to convert bytes to integers).

The designers of the *java.io* package decided to make some (but not all) I/O classes synchronized. In particular, the *read* methods of *BufferedInputStream* and the *write* methods of *BufferedOutputStream* are synchronized. This design leads to fairly fine-grained locking, particularly when small amounts of data are read or written at a time. An alternative design would be to leave the methods unsynchronized, and to instead require clients to ensure single-threaded access. Of course, since the latter approach places the burden of lock acquisition on the client, it requires more discipline. However, the benefit of the latter approach is that many lock acquisitions can be avoided, since the client can protect an entire I/O transaction with a single lock acquisition.

Unfortunately, many methods of the *DataOutputStream* class write data to the underlying stream a byte at a time. For example, the method *writeLong* performs 8 write operations to its underlying stream. In the typical case where the underlying stream is a *BufferedOutputStream*, a single call to *writeLong* results in 8 lock acquisitions! Similarly, writing the ASCII representation of an n-character string results

in *n* lock acquisitions. The *DataInputStream* class has exactly the same problems.

The *PrintStream* class is the standard way to write the string representation of a variety of types to an underlying stream[1]. As opposed to *DataOutputStreams*, *PrintStreams* write data to their underlying streams in larger chunks. For example, calling *PrintStream.print* causes a single *write* operation on the underlying stream. Unfortunately, the *PrintStream* implementation performs locking of its own. Printing out a string causes at least three lock acquisitions within the *PrintStream* implementation itself, plus any synchronization performed by the underlying stream.

The extra synchronization introduced by the core stream classes is not just an academic problem. Like many systems programs, Mercator writes extensive logs. For example, it writes a line to a log for every web page that it downloads. Using srcjava's synchronization profile, we discovered that writing one line to the log caused 67 lock acquisitions!

To work around the stream problems described above, we wrote a *BufferedDataOutputStream* class that combines features of *PrintStream*, *DataOutputStream*, and *BufferedOutputStream*. The class *BufferedDataOutputStream* is completely unsynchronized, placing the synchronization burden on its client. Using this class, writing a line to our download log requires only a single lock acquisition. We also wrote an analogous *BufferedDataInputStream* class that provides similar benefits.

Sun could address these performance problems by providing an unsynchronized variant of the *BufferedInputStream* and *BufferedOutputStream* classes, and by improving the implementations of the *DataInputStream* and *DataOutputStream* classes to perform fewer calls on the underlying stream. Although it is not documented in its API, *PrintStream*'s methods are thread-safe, so removing synchronization altogether is likely to break existing clients that have relied on this undocumented feature. However, the number of lock acquisitions required to print a string could be reduced from 3 to 1.

4.3 Host name resolution

Any program that contacts sites on the internet whose identities are provided in the form of symbolic host names must resolve those names into IP addresses. This process is known as *host name resolution*, and it is supported by the *domain name service* (DNS). DNS is a globally distributed service in which name servers refer requests to more authoritative name servers until an answer is found. Therefore, a single DNS request may take seconds or even tens of seconds to complete, since it may require many round-trips across the globe.

All common computing platforms provide standard routines for performing host name resolution. In Java, these are the *getByName* and *getAllByName* methods of the *InetAddress* class.

Mercator makes extremely heavy use of these methods. To avoid multiple downloads of the same document, a web crawler must maintain a set of discovered URLs. When Mercator extracts a URL from a web page, the URL is converted to a canonical form and then tested against the set. As part of the canonicalization process, the host name is resolved. Hence, Mercator performs a host name resolution for every link in every page it downloads. These requests are made in parallel by its 100 crawling threads.

Our initial measurements showed that host name resolution in Mercator was a severe bottleneck: it accounted for 87% of each thread's elapsed time. Upon studying the implementation of *InetAddress.getByName*, we discovered that it tries to avoid issuing costly DNS requests by caching the results of previous resolutions. However, we also found that the cache is protected by a single lock, which is held for the entire duration of the resolution. Hence, if one thread misses in the cache and therefore must contact a name server, any other thread attempting to resolve a host name will block until the first thread's request completes, even if the other thread's request could have been served out of the cache.

Our first attempt at rectifying this problem was to keep our own cache. The lock protecting our cache is held only while accessing or updating the cache, but *not* while calling *InetAddress.getByName* in the event of a cache miss. As a result, host names that are contained in our cache can be resolved immediately, even while calls to *InetAddress.getByName* are in progress. Unfortunately, such calls are still serialized by the lock in *InetAddress*. While this optimization improved Mercator's performance, host name resolution remained a bottleneck, since the rate at which Mercator discovers new hosts outpaces the rate at which host names can be sequentially resolved.

To overcome this problem, we implemented a DNS resolver in Java. Our resolver allows host name resolutions to be performed in parallel. It does not use *InetAddress.getByName*, but instead uses *DatagramSockets* to issue DNS requests directly to a local name server. Using our own resolver reduced the elapsed time spent by each thread on host name resolution from 87% to 25%[2]. More importantly, this change significantly increased the crawler's download rate.

Sun could address this problem by changing the implementation of the DNS cache not to hold a lock while performing DNS lookups. Perhaps an even more flexible solution would be to add a method that provides uncached DNS lookups without any locking, thereby allowing clients to implement

---

[1] The Java core libraries appear somewhat schizophrenic with regards to *PrintStreams*: although officially deprecated, they are still used for the standard output and error streams.

[2] Currently, when a worker thread processes a page, it extracts URLs from the page and canonicalizes them in sequence. We could further reduce the elapsed time spent by each thread on host name resolution by performing these canonicalizations in parallel.

their own DNS caching schemes or to bypass DNS caching altogether.

5. EXCESSIVE HEAP ALLOCATION

In Java, there are two costs associated with heap allocation. Aside from the direct cost of the *new* operation, there is also the cost of performing garbage collections (GC). The GC cost can be substantial, especially if the program has a high allocation rate. Moreover, most current Java runtimes (e.g. the Windows Sun/Symantec runtime and the Unix srcjava runtime) perform single-threaded, non-concurrent garbage collection. As a result, the garbage collection penalty is increased on multi-processor machines.

Although we cannot easily measure the allocation cost, srcjava can report the time spent on collections. Initially, Mercator spent 15% of its elapsed time performing collections. After making the optimizations described below, that time was reduced to 5%.

One problem with the Java core libraries with respect to allocation is that many objects cannot be reused. In some cases, it is possible to implement alternatives that allow object reuse. However, there are other cases where this is not possible, primarily because important native methods have been declared private, and are therefore inaccessible to any such alternative implementation. Given our philosophy of writing 100% pure Java code, we ruled out the option of implementing our own publicly accessible native methods.

FileInputStreams are one example of a class whose instances are not reusable. A *FileInputStream* object is associated with a file when it is constructed, but there is no mechanism for re-opening an existing *FileInputStream* on a different file. This means that the only way to access a different file is to allocate a new *FileInputStream* object. An alternative version of *FileInputStream* that avoids this problem cannot be written because the native method for opening a file is private to the *FileInputStream* class. The same remarks hold for *FileOutputStreams* and *RandomAccessFiles*.

Similarly, a *Socket* object is associated with a network connection at the time of its creation; it cannot be re-opened on a different connection. So, the only way to establish a new network connection is to allocate a new *Socket* object. Moreover, each *Socket* allocation causes the allocation of a *PlainSocketImpl*, a *SocketInputStream*, a *SocketOutputStream*, and a *FileDescriptor*. Again, it is impossible to write an alternative socket implementation because the native methods for establishing network connections are all private to *PlainSocketImpl*. Obviously, a web crawler like Mercator establishes many network connections per second. Due to the design of the *java.net* package, these connections cause hundreds of unavoidable allocations per second. Similar remarks hold for *DatagramSockets*, which we use heavily in our DNS resolver.

Like *FileInputStream* and *Socket* objects, instances of *BufferedInputStream* are not reusable. The *BufferedInputStream* constructor associates the stream with an underlying stream, and there is no mechanism for re-associating it with a different underlying stream later. So, accessing a new network connection via *BufferedInputStreams* requires the allocation of both a *Socket* and a *BufferedInputStream*, which in turn causes the allocation of a (potentially large) internal buffer.

However, unlike *FileInputStreams* and *Sockets*, it is possible to write an alternative version of *BufferedInputStream* that promotes object reuse through an *open* method, since *BufferedInputStream* has no native methods. We have implemented two such alternatives. One is the *BufferedDataInputStream* class mentioned in Section 4.2; the other is a class called *RewindInputStream* that is used to read web pages from network connections and buffer them. At the beginning of a crawl, we allocate one *RewindInputStream* object per crawling thread. These stream objects (and their large underlying buffers) are then reused throughout the life of the crawl.

Sun could foster object reuse by extending the stream and socket classes with methods for reopening them. In the *FileInputStream*, *FileOutputStream*, and *RandomAccessFile* classes, such methods already exist, but are not declared public.

In the examples described so far, the design of some classes in the core libraries prevented reuse of their instances. However, there are other classes, such as *StringBuffer*, whose instances are easily reusable, but whose points of use are widely scattered throughout the program, making it hard to identify an instance that can be reused. The same is true of *Formatter*, our *StringBuffer* replacement described in Section 4.1. To promote reuse of *Formatter* objects (and their internal buffers), we maintain a pool of unused *Formatters*. To avoid unnecessary synchronization when checking *Formatters* out of and back into the pool, we divide the pool into per-thread sub-pools. Once Mercator reaches its steady state, no new *Formatters* are allocated.

6. OTHER INEFFICIENCIES

In addition to the synchronization and allocation overheads described above, we have also discovered several other unrelated inefficiencies in the Java core libraries.

- The *java.io.RandomAccessFile* class is unbuffered, and no buffered variant is supplied. This means that every single read or write operation on a *RandomAccessFile* incurs the cost of a kernel call! To work around this problem, we wrote our own *BufferedRandomAccessFile* class. Our implementation is a subtype of *RandomAccessFile*, but it uses a buffering scheme that combines the designs of Modula-3's reader and writer abstractions [4]. Sun could provide a buffered variant of *RandomAccessFile* similar to ours as part of the *java.io* package.

- Constructing a new instance of *java.io.PrintStream* is quite expensive. After some investigation, we discovered that the *PrintStream* constructor indirectly performs dynamic class loading of a character converter class. As a result, constructing a *PrintStream* on our production runtime takes 366 ms elapsed time on average, which is over

5 orders of magnitude more expensive than constructing a *ByteArrayOutputStream*! We overcame the problem by using our own *BufferedDataOutputStream* class instead (see Section 4.2). Sun could improve *PrintStream* constructor performance by caching the *CharToByteConverter* associated with the current locale, rather than reloading it dynamically whenever a *PrintStream* is created.

It is worth mentioning that this anomaly did not effect Mercator's performance directly. Rather, it was hindering the performance of our synthetic proxy, which was constructing a new *PrintStream* on which to write the response to each newly received HTTP request. After removing the *PrintStreams* from our synthetic proxy, the rate at which the proxy could synthesize documents increased by a factor of 2.75.

- There are cases in the core libraries where two operations have similar semantics, but drastically different performance. For example, the *java.lang.String* class has six constructors for creating a string from a byte array. Four of them use byte-to-character converters to convert bytes to Unicode characters, while the other two take a byte as an argument and use it as the higher-order byte of each Unicode character. Despite the similarities of these constructors, the variants that use converters are 10 to 40 times slower, depending on the Java runtime.

  In Mercator, converting byte arrays to strings is a common operation, since web pages are downloaded as byte streams, but in the process of extracting links from HTML pages, parts of the byte stream are converted to strings. When we inadvertently introduced uses of the inefficient constructor into the link extraction code, Mercator's crawling rate dropped by a factor of 3!

- The *java.net* package provides networking facilities, including an implementation of the HTTP protocol. Our very first version of Mercator made use of this HTTP implementation. However, we soon discovered that it contains no provisions for specifying timeouts. As a result, an HTTP request will hang indefinitely if the remote server fails to close the connection, thereby disabling the calling thread. Surprisingly, such ill-behaved web servers are not uncommon. To work around this problem, we wrote our own streamlined HTTP implementation. Our version uses the *java.net.Socket* class, which *does* provide methods for setting timeouts. Sun could remedy this problem by adding methods to the *URLConnection* class for setting timeout values.

- Our initial implementation of Mercator used *java.net.URL* to represent URLs. However, we found that URL creation was relatively costly. By implementing our own URL class[1], we sped up the URL creation process by 25%–30%.

---

[1] Using our own URL class made sense only because we had written our own HTTP implementation.

7. CONCLUSIONS

We have used Java to implement a classical systems program, namely, a scalable web crawler. We found that the Java language is well-suited to such a task. Its object-oriented model and its package system support a modular programming style; its exception system makes it easier to build robust applications; garbage collection prevents memory leaks, making it easier to write long-running programs; and language-level thread support makes it easier to write multi-threaded programs. (Java shares all these attributes with Modula-3 [9], which has been our systems programming language of choice up until now.)

By sampling the hardware performance counters of the Alpha processor, we discovered that our system spends 63% of its cycles in the runtime or in native methods, and in fact 50% in the Unix kernel. We conclude that for I/O-intensive applications (which in Java result in a large number of native method calls), and in the presence of a reasonably good JIT compiler, Java is an attractive alternative to traditional systems programming languages such as C.

However, we also discovered that the Java 1.1 core libraries were designed for ease of use, not for speed. We identified numerous performance issues within the core libraries. Two of the root causes are excessive synchronization and excessive memory allocation, but we also discovered other inefficiencies. We were able to program around most, but not all, of these problems.

A cleaner solution would be to fix these problems in the core libraries themselves. For each of the problems we described, we have outlined how Sun could address them. The remedies we have proposed fall into three categories: providing unsynchronized variants of existing classes, improving the implementations of existing methods, and extending existing classes with additional methods. All the changes we have proposed would be backward-compatible with the existing Java 1.1 libraries.

Java's use a a development language for server-side applications is becoming more and more prevalent. The performance of such applications is often critical. One way to improve Java performance is to develop fast Java runtimes, and indeed, much research is being done in this area. Although such research is crucial, our experience shows that improving the performance of the core libraries is also important. We hope that Sun will therefore devote more effort toward improving the performance of the core libraries, and that it will augment the documentation of the libraries to highlight expensive method calls. Java's success as a systems programming language depends on it.
